Land rights, agricultural productivity, and deforestation in Vietnam

Ryan Abman¹ and Conor Carney²

August 2018

Abstract: This paper studies the relationship between land tenure for smallholder agriculture and deforestation in Vietnam. We combine high resolution satellite data on deforestation with rich household and commune-level, biannual panel data. We study two margins of tenure security, whether a household has any land title (extensive) and the share of a household's land held in title (intensive). Using a household-fixed effects model, we find the increases in crop production and land investment associated with holding land title are driven by the intensive margin. We then aggregate the survey data to the commune-level and find evidence that marginal increases in extensive tenure (share of households with any land title) increase deforestation holding constant the average intensive tenure (average share of land held in tenure among those with land title). We find some evidence that increasing the intensive margin of tenure (holding constant the extensive tenure) decreases deforestation. These results present a more nuanced view of the tenure-deforestation relationship than is prevalent in the existing literature.

1 Introduction

Land tenure may have both direct and indirect effects on deforestation. Research on the direct effects of land tenure has focused on the impacts of the security of property rights and ownership of land in the extraction of forest. Deacon (1994), Bohn and Deacon (2000), Ferreira and Vincent (2010), Robinson et al. (2014), Wendland et al. (2014), Wehkamp et al. (2018), and many others have shown that greater macro-level protection of property rights results in lower levels of deforestation. Under weak property right regimes there is an incentive to over extract natural resources that are less capital intensive, such as forest, or to clear land in order to establish a *de facto* property right when the *de jure* property right may not otherwise be enforced.

In addition, there are a number of indirect effects of land tenure on deforestation, but unlike the direct effects, the impacts of indirect effects are largely ex-ante ambiguous. There is a large body of research that links land tenure with improvements in agricultural productivity and land investment. Some notable examples include Feder (1987) for Thailand, Smith (2004) for Zambia, Markussen (2008) for Cambodia, Deininger and Jin (2006) on land related investment in Ethiopia, in addition to the Viet Nam-specific work we discuss in the following section.¹ If these land-related investments increase overall productivity, the returns to converting forest land to agriculture may increase and would thus lead to increased deforestation. However, if the land-related investments allow for more intensive agriculture (i.e. sustained perennial cropping rather than shifting cultivation of annual crops), deforestation could decrease. This tension is at the heart of the ‘Borlaug hypothesis’ - specifically, Borlaug hypothesized that increasing agricultural productivity would lead to less land in agriculture and thus less deforestation (Angelsen and Kaimowitz 2001). However, economic models of land clearing for agriculture often predict that increases in productivity increases the return for clearing land resulting in higher levels of deforestation (Angelsen 1999).

In this paper, we provide descriptive evidence on the relationship between land title, land investment, productivity, and deforestation in Viet Nam. We study this question using a combination of unusually rich household panel data on land title and agriculture as well as spatially explicit satellite data on deforestation in Viet Nam. In Viet Nam, many farmers work a combination of plots – some of which they hold a formal right to work, others they do not. Using household fixed-effects regressions, we find that land title is associated with intensive agricultural investments and increased output (consistent with the Borlaug hypothesis) but only when households have a large share of their land held in title. Furthermore, land used for forestry decreases for households when they hold large shares of land in title. However, we find that forestry production is greater for households who hold any land in title and local increases in titled land are associated with conversion to perennial crops.

From our survey data, we create a panel of three distinct measures of tenure, the share of households with any land title (extensive tenure), the average share of worked land in title among households with any title (intensive measure), and the share of surveyed land area with title across 368 communes. Combining these data with spatially explicit satellite data on forest loss, we find that increases in the extensive tenure margin are associated with increases in forest loss while increases in the intensive tenure margin are associated with decreases in forest loss, though the evidence on the intensive margin is weak. We find that, among a consistent sample of plots, increasing the titled share of surveyed land is associated with an increase in deforestation.

The contribution of the present paper is two-fold. First, we examine two margins of land tenure and estimate their effects on agricultural outcomes with implications for deforestation (extensification vs intensification). Second, we are able to relate these changes in title to observed changes in deforestation.

¹ See Lawry et al. (2017) for a recent, systematic review of this literature.

tion over the same time period while controlling for unobservable, time-invariant confounding factors. Other papers that have studied the relationship between land title, agricultural productivity, and deforestation have relied on cross-sectional variation in land title and forest cover (such as Liscow (2013)) or demonstrate agricultural expansion into historically forested areas (such as Kubitz et al. (2018)). The combination of our unique empirical setting and unusually rich panel data allows us to provide new evidence on the relationship between land tenure and deforestation.

The rest of the paper proceeds as follows. Section 2 provides background information on deforestation in Viet Nam as well as a discussion of the Viet Nam-specific literature on land tenure and agricultural investment and productivity. Section 3 describes the VARHS household data, our satellite data on deforestation, as well as our empirical approach taken in the paper. Section 4 presents the results found from our analysis and their implications. The paper concludes with some final remarks and directions for future work.

2 Land tenure, agriculture and deforestation in Viet Nam

Viet Nam is a unique country in the region for having gone through the forest transition, meaning net forest cover is actually increasing. However, much of the original old growth forest in Viet Nam has been lost to agricultural expansion, timber harvest, and the Viet Nam War. In 2010, nearly 25% of the forest cover was plantation with another 74% secondary growth forest - only 1% was classified as primary forest (Pham et al. 2012). Forest exports play an important role in the Vietnamese economy with the Ministry of Agriculture and Rural Development forecasting 2017 timber exports to reach \$7.5 billion.²

Despite the forest transition, deforestation in Viet Nam remains a concern. Between 2002 and 2009, 62,000 ha of forest was lost on average each year (Pham et al. 2012). According to Hoang et al. (2010), the primary drivers of deforestation in Viet Nam are land conversion for agriculture, land conversion for infrastructure projects (largely hydropower construction), unsustainable logging practices (both legal and illegal practices) and forest fires. There is considerable regional variation in these drivers as much of the conversion in the Northeast was driven by conversion to agricultural land for food crops, while conversion in the highland plateau driven by commercial and perennial crops, and forest land in the Mekong Delta converted to shrimp farms and aquaculture (Pham et al. 2012). Van Khuc et al. (2018) links cross-sectional variation in deforestation and forest degradation in Viet Nam from 2000 - 2010 to poverty, agricultural production, and local governance.³ Meyfroidt et al. (2013) demonstrate perennial crops displaced shifting cultivation of perennial crops into forest margins in the Central Highlands in this same period.

Understanding deforestation in Viet Nam warrants close attention to smallholder actions. Nearly 1/4 of Viet Nam's forests are owned by smallholders (single families) who are credit constrained and often forced to clear timber after only 5 years of planting, selling such timber earlier than optimal.⁴ These same credit constraints may also accelerate degradation which allows households to purchase agricultural

² <http://english.vov.vn/economy/ministry-predicts-wood-exports-at-us75-billion-this-year-350498.vov> (accessed on August 7, 2018)

³ However, Jadin et al. (2013) finds a weaker relationship between forest dynamics, poverty and agriculture in Northwestern Viet Nam.

⁴ <https://news.mongabay.com/2017/11/in-vietnam-small-farmers-and-timber-magnates-forge-uneasy-alliance/> (accessed on August 7, 2018)

input factors (Pham et al. 2012). Linde-Rahr (2005) finds that poor households are likely to turn towards extractive non-timber forestry to augment nutrition and short run income.

Land tenure has changed dramatically over the past 25 years in Viet Nam. Following the reunification of the country in the 1970s, land collectivization was widespread in both North and South Viet Nam. In the late 1980s, strict collectivization was relaxed to allow for individual certification within collective land areas. The 1993 land law extended these individual certificates to 20 years for annual crop production and 50 years for perennial crops. While the land remained nominally owned by the people and managed by the state, land use certificates resembled private land title, allowing owners to sell, mortgage, inherit, and lease certified land. The 2013 land law extended the time period for annual crop production to 50 years and further refined the individual's rights to use the land so long as the land was being used according to the regulations (Hirsch et al. 2015). In the early 1990s, the government also began the allocation of forest use rights to individual families. This program aimed to slow the slash and burn agricultural practices of farmers who did not have access to paddyland rights and was aimed at encouraging both forest protection as well as perennial plantations (Castella et al. 2006).

Economists have studied the role that land use certificates play in cropping decisions, land investment, and household consumption. Do and Iyer (2008) study the initial 1993 land law and argue that titling allowed households to switch to perennial crops and engage in more off farm income activities. Saint-Macary et al. (2010) find that land title increases investments in erosion control measures. Markussen et al. (2011) find that land restrictions do not reduce output, but require more effort and inputs from the household. Kemper et al. (2015) find land title increases both consumption as well as consumption volatility as land title allows for potentially risky investment for rural households. Markussen (2015) shows plot-level investment increases with land use certificates. Newman et al. (2015) find that joint land titling leads to higher land productivity. Promsopha (2015) finds that the land certificates provide important insurance for marginalized households. Of direct importance to deforestation, Saint-Macary et al. (2010) find that land title significantly increases the likelihood of practicing agroforestry (which reduces erosion, soil degradation, and landslide risk) in the Northern Highlands.

The closest work to the current study is Tachibana et al. (2001). The authors explicitly study land rights and extensification versus intensification. Looking at two study regions in Northern Viet Nam from 1978 - 1994 the authors find that titling of the upland regions prevented extensification from lowland agriculture and instead led to intensification and increased yields from existing lowland farms. Our paper departs from this study in a number of important ways. First, we study a period in Viet Nam after the 1993 and 2003 land reforms have taken place which drastically changed the nature of land rights in the country. Second, we look at individual household behavior as a function of the rights owned by the household itself. Such household data was not available to the researchers at the time of the earlier paper. Lastly, we are able to identify intensification/extensification from within household and within commune changes in land tenure due to the panel nature of our household and annual deforestation data. Tachibana et al. (2001) observe two periods of deforestation and estimate cross-sectional regressions.

That the land use certificates play such an important role in production investment decisions, crop choice, and household consumption provides the motivation we use to study tenure security's role in agricultural intensification/extensification and deforestation in Viet Nam. Below, we discuss the data and empirical approaches we employ to study this relationship.

3 Data and empirical approach

In this paper, we use a combination of panel survey data at the household and commune level and combine that data with spatially explicit satellite estimates of deforestation. We detail both of the key sources below.

3.1 Household data on land title, land investment and agricultural productivity

The first data set is the Vietnam Access to Resources Household Survey (VARHS). This panel survey has been administered every two years from 2008 through 2016 and includes information on a balanced panel of 2,131 rural households across 12 provinces and over 418 communes. The data have two main parts, a commune module which asks a local representative about aggregate commune indicators, and a household/plot-level module. In this paper we use data from the commune module for descriptive purposes (to show the relationship between perennial agriculture expansion, annual agriculture expansion, and expansion of residential areas on forest loss) but focus largely on the plot/household level measures of land tenure to study the relationship between land title, agricultural productivity and deforestation.

The variables in the data include key demographics about the household and its members as well as household characteristics that provide measures of land title, agricultural output, and agricultural practices. Specifically, we collapse plot-level data to the household level and calculate variables that measure certain agricultural practices such as how much land and the share of land that is: irrigated, in forestry, fallowed, and in perennials to create dependent variables of interest to understand the relationship between these agricultural practices and changes in land tenure security. We also examine agricultural output using data on the value of total crop production, and the value of perennial production. Additionally, we measure household land title in two ways. The first is whether a household has at least one plot on which they have a formal property right. The second is a continuous measure of the share of a household's total land that it has with a formal property right. (See Table 1 for summary statistics).

We analyze the household data to explore the mechanisms underlying the relationship between land tenure security and deforestation in Viet Nam. Theoretically, the effect of increasing land tenure on deforestation is ambiguous. Farmers will adjust their agricultural practices and/or shift cultivation to maximize output in response to the receipt of a land title. This can lead to an increase or decrease in deforestation depending on whether farmers expand and clear previously forested areas (extensive margin), or they alter their practices and focus on increasing yields on plots that are already deforested (intensive margin). We estimate the effects of increased land title on the share of land that is irrigated, in forestry, fallowed, and in perennials. We also examine productivity by estimating the effect of land title on the value of total crop production and the value of perennial production. The analysis of these outcomes are used to understand if the extensive or intensive margin is driving the relationship between land title and deforestation and what the underlying mechanisms are in this setting.

We create another measure of land title at the commune level through the use of the plot-level data in the VARHS. We restrict our sample to plots that are consistently observed throughout the sample period (thus creating a balanced panel). We then calculate the total plot area with title from that panel and use the ratio of the plot area with title to the total plot area. The province-level variation in this land title measure is presented in Figure 2. This measure has the advantage that changes in plots worked by households will not bias our findings and neither will disparities or inequality in household land under title.

These measures of title at the household and commune level are appropriate for studying productivity, land use, and land investment at the same scale in the VARHS data. However, we do not observe the explicit location of these plots or households – we only know the commune in which they are located. Thus, when we link these measures to our deforestation data, our results require the assumption that changes in patterns of land titling in our sample are representative of changes in patterns of land titling across the commune as a whole. This is an important caveat to our study.

The VARHS data do include a commune-specific module whereby they ask a local representative about the total area in the commune under different types of land use as well as the share of land in each use with title, the responses to the questions on land title are frequently missing (labeled as “Don’t Know” or “Not Applicable”) and those that are provided seem to lack precision and are likely indicative of guessing (the distribution has large spikes at round numbers such as 60 and 80% with almost nothing in between). While these measures may still be useful for broad, cross-sectional comparisons (areas with high shares of land title against those with low shares of land title) we believe the imprecision and missing values to be problematic for fixed effects regressions that rely on within-commune variation in land title. That said, we do use some of the commune-module responses to descriptively relate land use in perennial agriculture, annual crops, and residential area to forest loss.

3.2 Forest loss data

In order to measure forest loss, we use data from Hansen et al. (2013) that provides spatially explicit estimates of forest cover in 2000 and subsequent forest loss for 2001 - 2015 at an approximately 30m² resolution. Figure 3 presents examples of the underlying deforestation data. There are important caveats in working with these data that warrant discussion. First, tree cover is defined as the share of a pixel (30m²) that has vegetation at least 5 meters tall in 2000. This measure does not allow us to separately identify old growth forest from plantation and/or secondary growth forest. Thus clear-cutting of old growth forest and timber harvesting both register as forest loss equally. Furthermore, the dataset only registers the first time trees are cleared and does not account for tree growth that may replace those cleared. Thus, if a landowner clears trees in 2009 and then replants and clears again in 2014, the forest loss will only be registered in 2009.

We label individual pixels as ‘forested’ at baseline if the baseline tree cover is at least 15% of the pixel in order to reduce noise in our estimates. We then aggregate the count of pixels that are forested at baseline and lost in any given year to the commune level. This provides us with a panel of 15 years of deforestation across roughly 9,000 communes. We match by commune name the communes surveyed in the VARHS data and are able to connect 368 of the 418 communes in the VARS balanced panel. To match the time dimension of the biannual VARHS surveys, we take two-year averages of forest loss in communes such that a VARHS survey in year t is matched with the average deforestation from years $t - 1, t$. This is done because the survey month in year t varies from commune to commune and many of the questions refer to the previous calendar year. The result is a balanced panel of 368 communes across 5 different survey periods.

Figure 4 presents the geographic distribution of surveyed communes as well as baseline forest share at the district level. Surveyed communes are clustered throughout Viet Nam rather than evenly spread. We do have a good number of communes in the Central Highlands and Northeast regions, two areas with substantial natural forest that have faced significant deforestation pressure in recent years. Figure 5 presents district-level deforestation across the 15 year period of our tree cover data. It presents both the share of land area cleared as well as the share of baseline forest cover cleared. Figure 6 compares both baseline forest cover and forest loss by surveyed and non surveyed communes. The distributions are rather comparable between the two groups, which indicates that our surveyed communes are not

particular outliers either in forest cover or forest loss during this period. There do seem to be relatively fewer surveyed communes with no forest cover at baseline largely because the survey omitted urban communes.

3.3 Household analysis

To estimate the relationship between household land title and agricultural investment and productivity, we use two different measures of title. First, we use an indicator for whether a household has at least one plot with a land title. Next, we use a continuous variable that measures the share of total land for which a household has a formal land title. The effects of the first measure are estimated using the following household fixed effects model:

$$y_{i,t} = \beta_0 + \beta_1 \mathbb{1}[Title_Share_{i,t} > 0] + \gamma_i + \delta_t + \epsilon_{i,t} \quad (1)$$

where $y_{i,t}$ is a measure of agricultural practices or output value for household i in year t , $Title_Share_{i,t}$ is a continuous measure of the share of land with title for household i in year t , $\mathbb{1}[Title_Share_{i,t} > 0]$ is an indicator function equal to 1 if the household has any land in title and 0 otherwise, γ_i is a household fixed effect, δ_t is a year fixed effect and, finally, $\epsilon_{i,t}$ is the household-year error term.

Identification of β_1 in this model comes from within household changes in holding any title. Cross sectional differences among households that always hold title and those that never hold title will be accounted for through γ_i . As we do not have random assignment of land title nor do we have quasi-experimental variation in title, our estimates of the β_1 coefficient will measure how a household changes agricultural decisions when receiving some land title after previously holding none. Though these estimates are not causal effects, the household fixed effects and the year fixed effects (and the additional district trends and district by year fixed effects in other specifications) limit the degree to which our estimates will be driven by cross-sectional unobserved factors or other unobserved factors that change over time.

For our second measure of title, rather than force the relationship between share of land under title and the outcomes under study to be linear, we instead create bins according to the share of land under title. We then estimate the following household fixed effects model:

$$y_{i,t} = \beta_0 + \sum_{j=1}^4 \beta_j \mathbb{1}[Title_Share_{i,t} \in (0.25 * (j - 1), 0.25 * j]] + \gamma_i + \delta_t + \epsilon_{i,t} \quad (2)$$

where $y_{i,t}$ is a measure of agricultural practices or output value for household i in year t , $\mathbb{1}[Title_Share_{i,t} \in (0.25 * (j - 1), 0.25 * j]]$ is an indicator variable equal to 1 if the share of land in title is in $(0.25 * (j - 1), 0.25 * j]$ and 0 otherwise, γ_i is a household fixed effect, δ_t is a year fixed effect and, finally, $\epsilon_{i,t}$ is the household-year error term.

In this model, our β_j coefficients are identified from within household changes in the share of total land held in title and are individually interpreted as the effect of that particular share of land held in title relative to households with no land in title. The marginal effect of increasing the share of land in title from the lowest bin ($> 0, \leq .25$) to the next bin ($> .25, \leq .5$) is $\beta_2 - \beta_1$.

Again, the main threat to identification in our household analysis is that the decision to seek formal land title for a particular household is endogenous. Obtaining a formal title can be costly for a household and the benefits of the title might vary greatly across households. Therefore, we would expect households with lower costs of obtaining and higher returns to securing land title would seek out ways to obtain a formal land title for their plots. This would bias simple ordinary least squares (OLS) estimates of

β_1 and β_j 's. The household fixed effects eliminate this threat by controlling for all the time-invariant characteristics of the household that cause the OLS estimates to be biased. Additionally, we include year fixed effects, district time trends and district-by-year fixed effects in additional specifications to control for any additional time varying characteristics that might impact out results. Therefore, our underlying assumption is that there are no time-varying household characteristics that are also changing over the panel and are correlated with households increasing the amount of titled land they have.

3.4 Commune-level analysis

We use our third measure of land title in the VARHS data at the commune-level. This aggregates our balanced panel of plots to the commune-level, using the change in the share of this land as our explanatory variable in the following model:

$$y_{c,t} = \beta_0 + \beta_1 Title_Share_{c,t} + \gamma_c + \delta_t + i_{i,t} \quad (3)$$

In this case, our variation is at the commune-year level (rather than household-year level) and we examine the relationship between the share of land in title and the share of irrigated land, share of land in fallow, share of land in perennial agriculture, and the share of land in forestry.

Moving to our analysis on deforestation, our ideal empirical setting would analyze deforestation at the household level using the household land title status. Absent geographic coordinates for the households surveyed, we instead aggregate the household survey data to the commune-level to get commune-level averages in share of households with title (our extensive margin of tenure) and average share of land in title for those with title (our intensive margin of tenure). For these averages to be valid proxies for the actual title rates in the commune, we require the assumption that changes in household title patterns observed in our sample be representative of the overall changes in title in the commune more broadly. Due to the right-skewed underlying distribution of deforested pixels (see Table 6) we log transform the average number of pixels deforested over the two-year period corresponding to the survey timing. As such, we interpret our coefficient estimates as percent changes in average annual deforestation.

Our deforestation analysis begins with a descriptive fixed effects regression using the broader commune module land use estimates for the entire commune. We estimate the elasticities between perennial land area, annual crop land area, and residential area on deforestation. We then interact perennial area with province indicators to get province-specific elasticity estimates. These province-specific estimates are presented visually in the paper with the table of the estimates in the appendix.

We then estimate three different fixed effects models. The first examines the relationship between the extensive margin of tenure on deforestation and is as follows:

$$y_{c,t} = \beta_0 + \beta_1 Share_HH_Title_c + \gamma_c + \delta_t + i_{i,t} \quad (4)$$

The coefficient of interest is β_1 which captures the relationship between the share of surveyed households in a commune and the average annual log deforestation in that same commune. The inclusion of commune-specific fixed-effects (γ_c) controls for cross-sectional variation in average annual deforestation and land tenure which implies that our identification of β_1 arises from within-commune changes in the share of surveyed households with tenure. We control for changes in common year to year factors that drive deforestation with the inclusion of year fixed effects (δ_t). In additional specifications we include linear district time trends and district-by-year fixed effects to control for common time changes in a more flexible manner.

The above specification considers only the relationship between extensive margin of tenure and deforestation. We also estimate another model that accounts for both measures of tenure as follows:

$$y_{c,t} = \beta_0 + \beta_1 Extensive_c + \beta_2 Intensive_c + \beta_3 Extensive_c \times Intensive_c + \gamma_c + \delta_t + i_{i,t} \quad (5)$$

The extensive measure is the same as the variable of interest in equation (4), the share of households surveyed that have any land title. Our other measure of tenure, the intensive variable, is the share of land held in title among those who have any title in a commune. We include an interaction of the two measures as their effects on deforestation are likely dependent on one another. In doing so, the marginal effect of either the extensive or intensive margin is not simply the associated coefficient (β_1 for extensive, β_2 for intensive). The marginal effect of an increase in extensive tenure is $\beta_1 + \beta_3 Extensive_c$ and the marginal effect of an increase in intensive tenure is $\beta_2 + \beta_3 Intensive_c$. When we estimate the coefficients, we also present estimated marginal effects at the means and p-values for the test that these estimated marginal effects are zero.

Due to the inclusion of commune-level fixed effects, we identify these coefficients from within-commune variation in both measures of tenure. This requires that we have sufficient within variation in these measures. The within standard deviation for our intensive measure is 0.15 (with a mean of 0.87) and the within standard deviation for our extensive measure is 0.17 (with a mean of 0.69). Also, separate identification of the two effects requires that both measures are not perfectly correlated with one another. The two have a correlation coefficient of 0.44.

Because of the fixed effects we include in our model, time-invariant cross sectional omitted variables (such as distance to market, soil suitability for agriculture, etc.) do not pose a threat to identification. Furthermore, prevailing trends in land titling and deforestation will also not pose a threat to identification because these will be controlled for via our various time trends and time fixed effects. Our identification is undermined if there are omitted, time-varying factors that drive both land titling and deforestation at the local-level. Our identification also assumes that land clearing decisions are driven by land titling, and not the reverse. If land title required clearing land in order to obtain title (which is the case in some tropical countries) our model would be misspecified. Below, we discuss further why we believe our findings (at least partly) refute this potential reverse-causality issue.

Finally, we conclude our analysis with a commune fixed effects regression using the share of surveyed area with title as our explanatory variable. We include the same series of fixed effects as in our other deforestation models. Again, this model requires the assumption that changes in the share of land in title in our sample of plots is representative of changes in title for the commune as a whole.

4 Results

4.1 Land title and agricultural outcomes

The household-level results of increased land title on agricultural outcomes from estimating equation 1 are reported in Table 2. Each panel in the table presents the findings of a different outcome; log of forestry value, log of perennial value, log of crop value and the share of land irrigated. Each column presents results of a different model; (1) is the standard model from equation (1), (2) includes linear district time trends, and (3) includes district-by-year fixed effects.

We find that holding any land in title is associated with an 8 - 12 percent increase in annual value of forest product production. The value of perennial production increases by nearly 50 percent upon acquiring any land title, and total crop value increases by 22 to 25 percent. All of these findings are statistically

significant across all models with 11 of the 12 significant at the 5 percent level. Holding any land in title is associated with a two percent increase in irrigated land share. This finding however, loses significance upon inclusion of the district by year fixed effects. Taken together, holding any land in title is associated with increases in forest product production, agricultural production and land investments.

We visually present findings from our estimates of equation (2) using coefficient plots (full tables are in the appendix). Figures 8 and 9 present our estimates of the β_j coefficients from equation (2) with additional district-by-year fixed effects (thus akin to Column (3) in Table 1). To ensure that our estimated effects are not driven by households giving up untitled plots (thus increasing the share, but through changes in the denominator) we present both estimates of log crop value and crop value divided by the land worked, as well as log irrigated area and share of land irrigated.

These figures present a slightly more nuanced view of the relationship between land title and our outcomes. While these are consistent with our findings in Table 2, much of the intensification (investments in irrigation and increases in agricultural production) occurs at the higher end of the share of land in title ($> 50\%$). Below this 50 percent bin, crop production and irrigation are not statistically different from holding no land in title.

Figure 9 presents estimates of the relationship between share of land in title and forest practices. While forestry plays a relatively small role in our sample and declines through the sample period, it does have direct implications for tenure and deforestation. Our coefficient plots indicate that, at low levels of land in title, households have slightly more land in forest, but that this declines as the share of land in title becomes greater than 50%. There does not seem to be a difference in intensity of forest extraction as the forest value per forest land coefficients are all approximately zero. The finding on forest value then seems to be driven by differences in forest area rather than extraction intensity.

We present results from estimating equation (3) in Table 3. These commune-level results correspond to the aggregation across plots that comprise the balanced panel observed in the data. Our explanatory variable is the share of the plot area with title. In this table, we present only results for the base specification from equation (3), but results are largely similar upon the inclusion of province trends, and province-by-year fixed effects.⁵ We find that increases in the share of plot land with title are associated with increases in the share of irrigated land, increases in the share of land dedicated to perennial agriculture (though this result is just shy of statistical significance), and decreases in the share of plot area in forestry. We find no relationship between the share of land with title and the share of land in fallow.

4.2 Deforestation

We begin our deforestation results by using the data available in the commune module of the VARHS on estimates of total land use by type. Table 4 presents estimates of the relationship of log perennial area, log annual crop area, and log residential area on log average annual deforestation. Columns (1) - (3) estimate the relationships individually and column (4) includes all of them together. The estimates indicate that increases in perennial area are associated with increases in deforestation with small or zero effects on deforestation from increases in annual crop area or residential area. While these data have the benefit of providing estimates for the entire commune (rather than just those surveyed households or the surveyed plots) both missing values as well as imprecise estimates may undermine our ability for precise estimation and may lead to attenuation bias.

⁵ These results are available upon request.

We examine regional heterogeneity in the relationship between perennial land expansion and forest loss by allowing for province-specific coefficients on log perennial area. We present these results visually in figure 10 and include the tabulation of our results in the appendix. We estimate 4 specifications, one with commune and year fixed effects, another adding province-by-year fixed effects, a third with year fixed effects including log annual crop area and log annual crop area interacted with province indicators, and a fourth in which we add province-by-year fixed effects to the third model. We see the most consistent, positive effects (increases in deforestation associated with perennial increases) in the Northern Highlands with slightly more mixed results for the Central Highlands.

Next, we turn to our commune-level land title and deforestation analysis. Table 5 presents the estimates and associated standard errors from equation (4). Panel A uses the share of households that have any title and Panel B uses an area-weighted share of title as the independent variable. Column (1) presents estimates of the basic specification, Column (2) includes province-specific linear time trends and Column (3) includes province-by-year fixed effects. The estimates indicate that a 10% increase in the share of households with any land title is associated with a 1.6 - 2.7% increase in annual deforestation. The estimates struggle for conventional statistical significance in Columns (1) and (2) (though the p-value in Panel A column (2) is 0.117) but are significantly different from 0 at the 5% level upon the inclusion of province-by-year fixed effects, indicating that there is likely important year-to-year regional variation in deforestation across provinces in Viet Nam.

Figure 11 presents a coefficient plot of province-specific coefficient estimates from this model. While many individual estimates are not significantly different from zero, only two coefficients are negative (Lai Chau and Quang Nam), neither of which is significant with one of them being almost a precise zero (Lai Chau).

Table 6 presents results from estimating equation (5). As discussed above, we examine both extensive tenure (share of households surveyed that have any land title) and intensive tenure (average share of land with title among households who have any title). The coefficient estimates on the extensive measure and the interaction term are positive in all specifications and the coefficient on the intensive measure is negative yet none of these are individually statistically significant.⁶ We also present the marginal effects at the means for each measure. Because the marginal effects of one tenure measure depend on the level of the other, we use mean values for each measure when calculating marginal effects. Thus the marginal effect we present for an increase in the extensive margin of tenure is $\hat{\beta}_1 + \hat{\beta}_3 * 0.69$ and for the intensive margin is $\hat{\beta}_2 + \hat{\beta}_3 * 0.87$.

Our estimates for the marginal effects indicate that a 10% increase in the share of households with any land title (conditional on maintaining the existing average share of land in title) is associated with a 3.2 - 4.1% increase in average annual deforestation. However, a 10% increase in the average share of land held in title (holding constant the share of households that have title in a commune) is associated with a 1.2 - 4.2% decrease in average annual deforestation.⁷ We reject the hypothesis that the marginal effect at the mean for extensive change in tenure is zero at the 10% level for the first specification and at the 5% level for the other two. We can only reject the hypothesis of no marginal effect for the first specification (rejected at the 5% level). However, upon inclusion of province time trends and province-by-year fixed effects the estimated marginal effect becomes smaller and the standard errors increase dramatically.

While we make claims regarding the findings of the intensive tenure effects on deforestation cautiously, they nevertheless emerge as interesting. According to our household results, increasing the average share

⁶ The p-value on the individual coefficient on the intensive margin ranges between 0.12 and 0.16.

⁷ Estimating model (6) and omitting the interaction term yields estimated coefficients qualitatively similar to the marginal effects presented here both in magnitudes and statistical significance.

of land with title should lead to more agricultural intensification in ways that a simple increase of the share of households with any title would not. At the commune-level, these effects on deforestation are different – we reject the hypothesis of equality of marginal effects at the 5% level in all specifications. Furthermore, they provide evidence that the relationships we observe between title and deforestation are not driven by reverse-causality, otherwise both increasing margins of tenure would be positively correlated with deforestation.

Finally, we present results using the aggregated share of land in title from the balanced panel of plots in Table 7. While this measure does not disentangle the extensive vs intensive ownership margin as above, it does ensure that the sample plots are consistent through the period. Across the three specifications, we find positive associations between land in title and average annual deforestation with our most flexible specification indicating a 10 percent increase in share of surveyed land in title is associated with a 3 percent increase in average annual deforestation.

5 Concluding remarks

In this paper, we provide evidence that increased land title has a significant effect on household agricultural decisions and deforestation in Viet Nam. Specifically, using household fixed effects, we find that increased land title increases the value of both total crop production and perennial crop production as well as the share of land a household has under irrigation on both the extensive and intensive measures of land title. We also find that land title significantly decreases the share of land a household has in forestry, but only for the intensive measure of land title. We then collapse the data to the commune level and use a fixed effects regression model to demonstrate preliminary evidence that increases in our extensive measure of land title results in increased levels of deforestation. Additionally, we find that increases in our intensive measure of land title results in decreased levels of deforestation. These results suggest that the relationship between the share of land a household has land title for and deforestation is likely non-linear. Our results present a more nuanced view of the tenure-deforestation relationship than is prevalent in the existing literature although our overall effect suggests that increasing land title is associated with increasing deforestation.

Despite our efforts, the data limitations impose important caveats and limitations to our findings. First, as mentioned above, our deforestation results rely on the assumption that changes in household land title holdings in our sample are representative of overall changes in household land title holdings in the commune. In our final set of results, despite the fact that we have a balanced panel of plots in our analysis, we cannot empirically distinguish between forest loss that occurs on the plots we observe (as they change from forest to annual or perennial agriculture) vs forest loss that may be caused from indirect land use change from spillovers (as studied by Meyfroidt et al. (2013)). We acknowledge these caveats as important limitations to our study.

The relationship between land tenure and deforestation may be more complicated than simple extensification versus intensification as it is typically framed in the literature. Our findings that tenure increases intensification and productivity, but mainly for those who hold the largest share of their land in title, suggest a potential reduction in deforestation from increasing land tenure security. However, the conversion of land out of forestry and into agriculture associated with increased land title suggests that increasing tenure security may potentially increase deforestation. Overall, our results suggest that the latter effect dominates in Viet Nam, but there is suggestive evidence the former effect may still play a role.

Appendix

In this section, we discuss the appendix materials for *Land Rights, Agricultural Productivity, and Deforestation in Viet Nam*. Table A1 displays the province specific effects of commune level land use on deforestation. These results are displayed visually in Figure 10 in the text. We present four specifications, first is with province and year fixed effects, the second includes province and province-by-year fixed effects. Specifications (3) and (4) reproduce the first two, but also allow for province-specific slopes with annual crop land.

Tables A2 and A3, are the regression results that are used to produce the coefficient plots in Figures 8 and 9. All models include household fixed effects and district-by-year fixed effects. They show the nonparametric relationship between land tenure land use. Again, these results suggest that much of the intensification (investments in irrigation and increases in agricultural production) occur at the higher end of the share of land in title ($>50\%$). Additionally, we find that forest results are driven by differences in forest area rather than extraction intensity.

Commune FEs	Yes	Yes	Yes	Yes
Year FEs	Yes	No	Yes	No
Province-by-Year FEs	No	Yes	No	Yes
Province-specific Annual Crop control	No	No	Yes	Yes
No Obs	1808	1808	1789	1789
R ²	0.036	0.269	0.042	0.274

Notes: The outcome in all columns is the natural log of 1 + the average annual number of pixels cleared within the commune. Columns (1) and (2) present province-specific estimates of the relationship between log of perennial land in a commune and forest loss while Columns (3) and (4) include province-specific estimates of the relationship between annual land under cultivation and forest loss. Long An is the only province that has a statistically significant relationship between annual crop area and forest loss with estimated elasticities of 0.115 ($p < 0.1$) and 0.110 ($p < 0.01$) for columns (3) and (4) respectively. Standard errors are clustered at the commune level and are in parenthesis. Asterisks applied as follows:

* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Authors' calculation based on data from VARHS and Hansen et al. (2013).
